Executive summary

The Australian Institute of Health and Welfare (AIHW)\(^1\) described potentially avoidable hospitalisations (PAHs) as “admissions to hospital that could have potentially been prevented through the provision of appropriate non-hospital health services”. The AIHW\(^1\) classify PAHs into three main types: Vaccine-preventable, chronic and acute conditions. In 2009-10, PAHs related to chronic conditions were the most common, due mainly to the high rates of hospitalisations for diabetes complications (24% of all PAHs).\(^1\) Moderately high rates of PAHs were also reported for chronic obstructive pulmonary disease (COPD), dehydration and gastroenteritis, and dental conditions (9-10% of all PAHs).

Several independent groups of researchers have shown that poor access to primary health care is strongly related to higher rates of PAHs.\(^2,3,4,5\) In Australia, data on PAHs are collected routinely by the AIHW\(^6\) and used as an indicator of primary health care accessibility and effectiveness.\(^7,8\)

However, it is important to note some limitations and caveats pertaining to PAHs data and interpreting analyses:

- **Accuracy of PAHs estimates.** In an extensive review of the literature, the Agency for Healthcare Research and Quality (AHRQ)\(^9\) stated that it is often difficult to accurately determine the extent to which PAHs are avoidable, particularly in chronic conditions where there is inevitable physical deterioration.
- **Variations in coding for PAHs.** The statistical reliability of data on PAHs varies due to differences in the way data are coded across hospitals.\(^6,10\)
- **Reliability of PAHs as an indicator of primary health care access.** The AHRQ suggest that PAHs should be analysed and interpreted as a set, rather than in specific disease groups as statistical analyses becomes less reliable where there are small numbers of people with a particular condition.\(^9\)
- **Level of access to primary health care.** Weinberger et al.\(^11\) cautioned that higher rates of hospitalisation are not necessarily due to poor access to primary care, but may reflect better access. That is, hospitalisation may occur as a result of better detection of impairments in the primary health care setting.
- **Role of other factors.** Beyond access to primary health care, socioeconomic disadvantage,\(^12\) rurality,\(^1\) comorbidities\(^13\) and certain immutable factors, such as age,\(^14\) gender\(^15\) and ethnicity\(^16\) are also associated with high rates of PAHs.

Reducing the rates of PAHs in Australia is a key objective in several important Australian Government health care agreements: Australia’s National Health Performance Framework\(^17\), the National Strategic Framework for Aboriginal and Torres Strait Islander Health (NSFATSIH).\(^18\) and the Council of Australian Governments (COAG) National Healthcare Agreement.\(^19\) To address this objective, a number of initiatives have been implemented in States and Territories and nationally, with varying degrees of success.

This report reviews the available research evidence on the impact of initiatives to reduce PAHs. While many health reform policies and initiatives have been implemented, only those that have been evaluated for their effectiveness in reducing PAHs have been included in this report.
Initiatives to reduce potentially avoidable hospitalisations (PAHs)

An extensive review conducted by the Clinical Epidemiology & Health Service Evaluation Unit in Melbourne reported that most large-scale initiatives focused on reducing PAHs in people with chronic conditions. However, although the AHRQ recommended that PAHs should be treated as a set if they are to be used as an indicator of primary health care access, evidence from a systematic review suggests that interventions to reduce PAHs are more effective when they target specific conditions, rather than taking a large-scale policy approach.

This report focused on interventions for three of the most common conditions (identified by AIHW) that resulted in PAHs: diabetes complications, COPD and dental problems. Table 1 provides a summary of the risk factors for PAHs and effective programs to reduce PAHs in patients with diabetes complications or COPD.

Dental conditions

Dental health is integral to overall health status and dental conditions underlie approximately nine per cent of all PAHs in Australia. There is a strong relationship between poor oral health and socioeconomic disadvantage. Although there was no available evidence pertaining to the effectiveness of primary dental care and reductions in PAHs, there was evidence to indicate that poor access to dental care was related to increased hospital admissions for preventable facial infections. A suite of oral health initiatives have been proposed and some have commenced (See Appendix D Oral health initiatives); however, evaluations are not yet available.

Populations with high rates of PAHs

It is well-accepted that Indigenous Australians and people from low socioeconomic backgrounds often have difficulty accessing primary health care, have poorer overall health, and higher rates of hospital admissions, particularly PAHs. However, research evaluating the effectiveness of
interventions designed to reduce PAHs in these populations is scarce. Some research indicates that the likelihood of hospitalisations can be reduced using multifactorial approaches\textsuperscript{42,43} as listed in Table 2.

Avoidable hospital readmissions

Readmissions to hospital are also common, costly and often avoidable.\textsuperscript{46} Some research suggests that initiatives involving enhanced discharge and follow-up procedures (to primary health care and community settings) may contribute to lower rates of avoidable readmissions.\textsuperscript{47}

While the research evidence in this area is sparse and relatively weak, the common characteristics of some promising interventions to reduce avoidable hospital readmissions include:\textsuperscript{47,48}

- **Algorithm to identify high-risk patients**: eg. LACE Index\textsuperscript{46}, Patients At Risk of Readmission (PARR) algorithm\textsuperscript{49}
- **Patient education**: eg. tailored instructions; Teachback technique to confirm patients’ understanding of care plan
- **Comprehensive discharge planning**: pre- and post-discharge communication with patient’s provider and caregivers
- **Scheduled follow-up**: telephone communication with patients post-discharge; follow-up appointments.
Conclusions
Targeting reduction in PAHs is a specific objective of health care reform in Australia, with the aim of improving patients’ outcomes, reducing pressure on hospitals and enhancing health system efficiency and cost-effectiveness.

This review identified several promising programs to reduce PAHs in chronically ill Australians. Common characteristics of effective initiatives included:
- early identification of patients who are at risk of hospitalisation
- care coordination and integration of services
- enhanced access to primary health care and focus on equity
- multidisciplinary care team
- disease management, particularly for medium to long-term.

Importantly, it should be noted that reductions in PAHs are not necessarily associated with improved clinical outcomes. In addition, where hospital admissions decrease, the burden on primary health care may increase and resources will be needed to support the demand.
Introduction

The Australian health care system is currently experiencing increased demand due to an ageing population, increase in chronic conditions, and higher expectations regarding service delivery. In the short term, this is manageable. However, projections indicate that managing the demands on the health care sector in the long term presents a significant challenge.

One approach to reduce this unsustainable health care service demand (and associated costs) is to shift the service delivery focus from the acute to the primary health care sector, thus avoiding costly hospitalisations. A stronger focus on primary health care will not only reduce costs and demand on hospitals, but will also alleviate the significant distress that patients experience when they are hospitalised for a condition that has reached a level requiring an acute care response.

This report focuses on the use of potentially avoidable hospitalisations (PAH) as an indicator of primary health care accessibility and effectiveness. It reviews the relevancy of PAHs as an indicator of primary care effectiveness and the key contributors to PAHs in Australia. Finally, the report reviews interventions, programs and initiatives that mitigate PAHs in Australia and internationally. Although reducing PAHs is a key aim of a range of different health reforms, from the policy level through to clinical settings, this review included only the initiatives that have been evaluated in terms of their effectiveness in reducing PAHs.

Rationale for PAHs as an indicator of primary health care efficiency and effectiveness in Australia

The idea of measuring PAHs as a litmus test for the efficiency and effectiveness of the primary health care sector was introduced in the early 1990s. Since then, PAHs have attracted a high level of interest from researchers and policy makers alike, most recently in Australia. Currently, PAHs are included in the objectives of Australia’s National Health Performance Framework and the National Strategic Framework for Aboriginal and Torres Strait Islander Health (NSFATSIH).

Australia’s commitment to reducing the rates of PAHs has been articulated most recently in a Council of Australian Governments (COAG) agreement. This COAG agreement set nine performance benchmarks for the National Healthcare Agreement. The seventh of these aims to reduce the proportion of PAHs by improving primary health care so that it equates to 8.5 per cent of total hospital admissions by 2014-15.

Method

This report followed a ‘rapid review’ format. Rapid reviews are short literature reviews that focus on research evidence, with a view to facilitating evidence-based policy development. Due to the short timeframe for this review (8 weeks), searches and critical appraisal of the literature were not systematic or comprehensive. In order to obtain the most relevant material quickly, search terms varied across different databases. Consequently, replication of this review may result in a different literature base.

The issue under investigation centred on interventions to decrease the rates of PAHs. Specifically, this review sought to address the following:
What does the local and international research literature tell us about hospital admissions that are potentially avoidable related to improved primary health care service delivery, including measures of success, causation and pathways?

The literature search was not limited by time period, as much of the research on PAHs was conducted in the early 1990s. Likewise, no limits were placed on location or setting, though research undertaken in notably different environments such as the US, or within Health Maintenance Organisations have been flagged as such. Only initiatives that were evaluated for their impact on reducing PAHs were included. Both grey and peer reviewed literature were included in this report.

A range of definitions have been used for PAHs depending on the context and country. Examples include “ambulatory care sensitive conditions”, “potentially preventable hospitalisations” or “potentially avoidable hospitalisations”. The approach used in Australia (including the Health Performance Framework and AIHW) is based on the “potentially avoidable hospitalisations” framework. While there may be some differences in definitions, most research uses the terms interchangeably. Therefore, for consistency throughout this report, we have used PAHs, which are defined as:

... certain conditions for which hospitalisation is considered potentially avoidable through preventive care and early disease management, usually delivered in a primary care setting, for example by a general medical practitioner, or at a community health centre.

Although the search strategy for this review did not specifically include avoidable hospital readmissions, there was some overlap in the literature and some evidence to suggest that readmissions to hospital may be prevented through appropriate primary health care post-discharge. Therefore, a brief section on avoidable hospital readmissions has been included in this report.

Full details of the methods used in this review are available in Appendix A Expanded methods.

**PAHs and their prevention**

**The concept of PAHs**

Early research on PAHs originated in the US in the 1990s, when two groups of researchers developed disease- and condition-based lists of PAHs. First, Weissman and colleagues proposed a set of 12 conditions for PAHs in 1992. One year later, Billings developed an expanded set of 28 conditions for PAHs, which included those in Weissman’s classification. Billings’ conceptualisation is used most widely in the research literature, as well as in the Australian policy environment (such as the Health Performance Frameworks). Regardless of the classification system, both sets were confirmed by a panel of physicians. Each definition stipulates that certain disease-specific hospitalisations are avoidable if patients receive appropriate primary health care, particularly by:

- immunisation
- preventing the onset of a condition
- early detection
- controlling a condition
- managing an ongoing chronic condition
- appropriate interventions of an acute condition.

---

a Although these terms have different meanings, a comprehensive explanation of the differences is beyond the scope of this review. For more information on the difference between these definitions see.
PAHs\(^b\) are categorised broadly into three types:\(^c\)\(^d\)

- **Vaccine-preventable:** good access to health care services may reduce the incidence of preventable diseases.
- **Acute:** timely and appropriate primary health care may reduce morbidity and pain and prevent a condition from worsening and leading to hospitalisation.
- **Chronic:** effective primary health care management may reduce effects of chronic disease and prolong life.

Most PAHs are relatively common hospital admissions, such as influenza, asthma and diabetes complications.\(^a\) A summary of conditions included in the National Performance Framework is shown below in Table 3, with a full list of conditions provided in Appendix B *Avoidable hospitalisations included in the Australian Health Performance Framework*.

### Trends in rates of PAHs

Increasingly, PAHs are seen as an important indicator of primary health care accessibility and effectiveness. This has led to regular data collection that allows for examination of trends and regional comparisons. Over time, the numbers of PAHs have decreased from a peak in the 2007-08 period, where 33.3 (per 100,000) hospital separations were attributable to PAHs (see Figure 1 below).\(^c\)

\(^b\) Classification for ACSCs (Ansari, 2007). For consistency and to avoid confusion, PAHs are used here.

\(^c\) The Productivity Commission\(^e\) issued the following statement regarding longitudinal comparisons of diabetes data “Caution should be used in comparing these data to earlier years as changes between ICD-10-AM 5th edition and ICD-10-AM 6th edition and the associated Australian Coding Standards apparently resulted in decreased reporting of additional diagnoses for diabetes, and increased reporting of gastroenteritis (chronic and acute categories, respectively, affected).”
The rates of PAHs are also affected by geographical location. Remote areas experience much higher rates for all types of PAHs, as shown below in Figure 2.

There is also substantial variation between the States and Territories of Australia. Western Australia has the highest proportion of PAHs, whereas the Australian Capital Territory has the lowest rate (see Figure 3).
PAHs as an indicator for primary health care effectiveness

PAH is often used as an indicator of access to primary health care, particularly at an area level.\textsuperscript{59}

General caveats

The extent to which PAHs are avoidable is difficult to measure or estimate.\textsuperscript{9} It must be noted that events that are classified as PAHs are not always avoidable. Indeed, in some cases where there is inevitable physical degeneration, such as in COPD, it may be appropriate for hospitalisation to occur.\textsuperscript{9}

A full discussion of this issue is addressed in the following section on Factors that promote or inhibit rates of PAHs.

Given the number of factors that can affect rates of PAHs (beyond accessibility to primary health care), the interpretation of statistics regarding rates of hospitalisation should be treated with caution. An extensive US review of PAHs as an indicator of primary health care effectiveness recommended that PAHs should be interpreted as a set rather than examined as individual, disease-specific groups.\textsuperscript{9} This is due in part to statistical unreliability that occurs when there are small numbers with a particular disease.\textsuperscript{9} This review also suggested that most indicators should be adjusted for demographic factors, such as the age of the population in a particular area as both older age and rurality are risk factors for PAHs.\textsuperscript{9,60} In particular, all vaccine-preventable and most acute PAHs should be treated as a set, with a view to developing targeted interventions delivered at the local level.\textsuperscript{59}

It is also worth noting that higher rates of hospitalisation for PAHs are not always indicative of poorer access to primary health care. Higher rates of hospitalisation may represent better levels of primary health care, rather than deficiencies, as more impairments may be detected in the community.\textsuperscript{11}

Caveats in Australia

Data on PAHs are collected by the Australian Institute of Health and Welfare (AIHW)\textsuperscript{6} from almost all public hospitals and most private hospitals in Australia. Data are coded according to the patient’s usual address, and exclude emergency department presentations and services provided on an outpatient basis.

Figure 3 Proportion of hospitalisations that are avoidable, disaggregated by State and Territory\textsuperscript{6}
The validity of data for this indicator depends on the way in which patients’ illnesses or conditions are coded on admission to hospital. Differences in the way that clinicians code these admissions, both within and across hospitals, result in variations in reported statistics. In addition, hospitals differ in their admission policies, and this may also affect the rates of reported PAHs.

Factors that promote or inhibit rates of PAHs

**Accessibility of primary health care services**

Rates of PAHs are often used as an indicator of the accessibility of primary health care. As Gresenz notes: “While a range of factors contributes to [PAH] rates, evidence suggests that a key determinant is the availability of primary care.”

Indeed, many studies show that access to primary health care is strongly associated with the rates of hospitalisation for avoidable conditions. Evidence supporting the link between accessibility to primary health care and rates of PAHs come from a number of different sources, including higher rates of avoidable hospitalisation when there is:

- Poorer self-reported access to medical care
- Higher costs for the consumer
- Lower ratios of GPs to population
- Increasing socioeconomic disadvantage
- Lower numbers of GP consultations
- Greater remoteness

However the degree to which PAHs are actually avoidable differs according to the timeliness and appropriateness of interventions in primary health care. In addition, a range of factors beyond access to primary health care services may promote or inhibit the rates of avoidable hospitalisation.

**Other factors**

While it is acknowledged by most researchers that there are numerous factors other than accessibility that lead to an avoidable hospitalisation, models to test the combination of factors have not been articulated in the peer-reviewed literature. Research has focused primarily on single factors and their association to the rates of PAHs. These factors are described in Table 4.

Each of these factors interacts to produce multilayered risk or protective factors. It is also difficult to separate the many factors that act as proxies. For example, air quality is associated with higher rates of PAHs. However, given that air quality tends to be lower in more disadvantaged areas, it is difficult to separate the effects of air quality versus SES on PAHs.

Potentially avoidable hospitalisations in Australia: Causes for hospitalisations and primary health care interventions

Initiatives to reduce PAHs

Overview

The AIHW\(^1\) identified three sub-types of PAHs: vaccine-preventable, acute, and chronic conditions. In 2009-10, chronic conditions were the most common type of PAH. This was largely due to high rates of diabetes complications, which comprised approximately 24 per cent of all PAHs. Other conditions for which there were high rates of hospitalisation included COPD, dehydration and gastroenteritis, and dental conditions. Table 5 shows the numbers of PAHs in Australia in 2009-10.

[Source: AIHW, 2010]

The following sections present evidence of effectiveness for two types of approaches:

1  Large-scale initiatives: Interventions that have been implemented generally to people with a chronic disease or acute condition
2  Disease-specific initiatives: Interventions that have targeted populations with a specific condition.

\(^d\)Note that the totals are not the sum of the counts of the PAHs. It is believed that this is due to numerical randomisation initiated by AIHW to preserve patient confidentiality. AIHW was contacted for further information but no further information could be obtained.
Other approaches, which may be implemented as a secondary means to avoiding hospitalisation, involve improving access to primary health care and health promotion. A discussion of these approaches is provided in Appendix F *Other approaches to reduce PAHs*.

**Large-scale health interventions to reduce PAHs**

A number of policies that have been developed at the national and State or Territory levels directly or indirectly aim to reduce the rates of PAHs. These policies differ in the extent to which they identify reduced hospitalisation for PAHs as a successful outcome of the policy.

Policies or initiatives also differ in the type of PAHs they target: vaccine-preventable conditions, chronic conditions or acute conditions. In a large research project, the CEHSU\(^2\) interviewed key informants and conducted a search to identify policies or initiatives aimed at reducing PAHs. The types of PAHs these policies and initiatives target are shown in Table 6. A full list of the policies can be found in Appendix C *Policies that focus on reducing PAHs*.

[Source: CEHSU, 2009]

It is worth noting that many of these initiatives may have articulated avoiding PAHs as the rationale for the policy, however they did not evaluate them as an outcome measure. Those that did use rates of PAHs as an outcome measure are presented below in Table 7, including results of the evaluations.
### Table 7  Policies or programs that focus on reducing PAHs

<table>
<thead>
<tr>
<th>Policy/Program(^6)</th>
<th>Target population</th>
<th>Key features of the program or policy</th>
<th>Evaluation findings(^1)</th>
</tr>
</thead>
</table>
| NSW Chronic Care Program\(^3\) | General population with chronic disease (and their carers) | • Patient-centred approach to service delivery  
• Build patient self-management capacity  
• Focus on timely access to care  
• Promote health service integration for patient continuity of care  
• Develop systems to promote long-term management of care. | As a proportion of all NSW admissions, data showed:  
• Heart failure admissions were significantly lower for October, November and December in 2004 than for the same months in 2003.  
• COPD admissions were significantly lower in November and December 2004 than for the same months in 2003, though in May and October there were significant differences in the opposite direction. |
| NSW Community Acute Post-Acute Care (CAPAC) Service\(^3\) | General population with selected acute and chronic conditions | • Multidisciplinary clinical care to people in the community to manage their condition at home and prevent deterioration  
• Clinical care to patients who have had an operation and can be discharged early to recover at home rather than in hospital. It is generally only for the short term (5-14 days).  
• “Hospital in the Home” Initiative. | • Approximately 45 000 patients per annum were treated through the CAPAC program at half the cost of inpatient treatment.  
• For some medical conditions, length of stay was reduced for an average of 2 days.  
• In a metropolitan Sydney hospital with an established CAPAC program, 30% of cellulitis presentations to the ED were seen by the CAPAC service, avoiding admissions to hospital which equated to 741 bed days saved.  
• For acute complex respiratory conditions, admissions reduced from 4 per annum to less than 1 per annum. Length of stay reduced from 6.9 days to 4.2 days. |
| HealthOne NSW\(^108\) | General population with chronic conditions | • Integrated care provided by general practice and community health services (and other services – allied health, specialists) | This is currently being evaluated by Professor Steven Leeder, University of Sydney. Anecdotal evidence suggests the model is successful - |

\(^6\) Only programs that have been evaluated, or are being evaluated, are included here.

\(^1\) Note: only the avoidable hospitalisation findings are reported here. See evaluations for the full results.
| **NSW Healthy at Home**<sup>59</sup> | Frail older people in the community, aged over 65 years (over 45 years for Indigenous people) | • Referral Information Centre  
• Rapid response health service teams  
• Case management services  
• Case managed package of care for up to 6 weeks. | Promising results were reported. However, the quality of the evaluation was poor, due largely to a lack of planning for evaluation at the outset of the program, and an inability to obtain patient data (including hospitalisation data). It was estimated that 79% of clients would have been hospitalised had they not been referred to this program. |
| **Victoria: Hospital Admission Risk Program Chronic Disease Management (HARP CDM)**<sup>23</sup> | People with chronic heart disease, chronic respiratory disease, diabetes, complex psychosocial needs and older people with complex needs | HARP was implemented through a series of competitively funded community and hospital based projects and comprises a range of prevention initiatives that have the potential to affect hospital emergency demand. These include:  
• Comprehensive assessment and individualised care planning  
• Comprehensive transition and discharge planning  
• Secondary preventive care  
• Ongoing monitoring and review  
• Specialist medical and GP management  
• Self-management advice  
• Other specialist and allied services where needed.  
• After-hours support  
• Multidisciplinary team care  
• Carer involvement | Overall HARP has resulted in:  
• 35% fewer ED attendances  
• 52% fewer ED admissions  
• 41% fewer days in hospital  
The reduced need for hospital services was equivalent to approximately one ED attendance, 2 ED admissions, and 6 days spent in hospital each year for every HARP patient.  
HARP patients with multimorbidity experienced:  
• 49% fewer ED attendances  
• 61% fewer ED fewer emergency admissions  
• 57% fewer days in hospital.  
There was no difference in the pattern of ongoing hospital use (presentations, admissions and number of nights spent in hospital) for both HARP and non-HARP patients with CHF. |
| **Victoria: Early Intervention in General population with chronic** | This program developed a set of models, with leadership from community health services and | Patient self-reported health care utilisation (in 12 month prior) was collected, and showed that |
| Chronic Disease in Community Health (EliCD)\textsuperscript{110} | conditions who are at high risk of hospitalisation in medium to long-term | Divisions of General Practice that target people with chronic conditions.  
- Multidisciplinary care team  
- Patient education  
- Care coordination  
- Self-management support  
- Flexible service delivery and models of care tailored to needs of local population. | hospital admissions decreased slightly from 199 (30.0%) at baseline to 88 (27.2%) at 6 months; but had increased slightly for chronic disease admissions from 58.7% to 63.6%. |
| Most States and Territories have programs that provide hospital care in the home: Hospital in the Home (HITH)\(^9,111,112\) | General population with selected acute and chronic conditions | A multidisciplinary team of health care providers (eg. doctors, nurses, physiotherapists) provide treatment services for patients in their own homes. Patients may be eligible for the program without being admitted to hospital; or they may be discharged early to receive ongoing treatment at home.\(^{113}\) | Evidence from systematic reviews suggested that mortality, morbidity and hospital readmissions were not significantly different between HITH and hospital care. HITH patients had:
- Decreased length of hospital stay
- Higher levels of satisfaction
- No increase in carer burden

No evidence of lower cost-effectiveness.\(^{114}\) |

---

\(^9\) Also known as Hospital at Home or Home-based primary health care.
Disease-specific initiatives
As stated previously, the ARHQ recommends that avoidable hospitalisation statistics should not be interpreted on a disease-by-disease basis, as the indicator was developed to measure access to primary care. However, many interventions to reduce PAHs respond well to condition-specific interventions and lack of disease or population specificity is a key criticism of large-scale policy approaches to reducing PAHs.

PAHs for diabetes complications
Hospitalisations for people experiencing diabetes complications are problematic in Australia and around the world. In Australia, diabetes is the most common condition for which hospitalisation may be avoided. Patients who are hospitalised due to diabetes are also more likely to have extended hospital stays, and multiple hospitalisations.

Responsibility for the care of people with diabetes has shifted from hospitals to primary care, with multiple studies demonstrating that care in primary health care settings can be as good as hospitals, improve disease status, and reduce PAHs. While diabetes complications were the most common presentation in Australia, most research on diabetes and PAHs is from overseas, with some Australian studies undertaken in Victoria. Diabetes complications accounted for 23.8 per cent of all PAHs across Australia. Although the number of avoidable hospitalisations has steadily decreased from 9.9 (per 1 000) reported in 2005-06 to 7.1 (per 1 000) in 2009-10, there have been changes in the coding of diabetes in the ICD, and this decrease should be treated with caution as it may not represent a real drop in admissions.

Certain factors are likely to increase the likelihood of presenting to hospital for diabetes complications. These are shown in Table 8.

<table>

<th>Factors associated with an increased risk for diabetes PAHs</th>
</tr>
</thead>
<tbody>
<tr>
<td>Factor</td>
<td>Explanation</td>
</tr>
<tr>
<td>Rurality</td>
<td>PAHs were much lower in major cities compared to more rural areas. Admission rates for diabetes complications were higher in rural areas compared to metropolitan Melbourne.</td>
</tr>
<tr>
<td>Socioeconomic status</td>
<td>PAHs in the lowest SES group were more than twice as likely as in the highest SES group.</td>
</tr>
<tr>
<td>Comorbidity</td>
<td>Comorbidity complicates the diagnosis and treatment of diabetes and other complications, particularly in the elderly.</td>
</tr>
<tr>
<td>Depression</td>
<td>Depression is associated with a high risk of hospitalisation, even when controlling for age, gender and other demographics. Treating depression reduces this risk through improved self-management.</td>
</tr>
<tr>
<td>Socioeconomic status or disadvantaged subpopulations</td>
<td>Diabetes hospitalisations show a clear association with the socioeconomic gradient.</td>
</tr>
<tr>
<td>Indigenous status</td>
<td>From July 2006 to June 2008, diabetes complications were the most common type of ambulatory care sensitive condition among Indigenous Australians, who were hospitalised at around eight times the rate of other Australians.</td>
</tr>
</tbody>
</table>

The Productivity Commission issued the following statement regarding longitudinal comparisons of diabetes data “Caution should be used in comparing these data to earlier years as changes between ICD-10-AM 5th edition and ICD-10-AM 6th edition and the associated Australian Coding Standards apparently resulted in decreased reporting of additional diagnoses for diabetes, and increased reporting of gastroenteritis (chronic and acute categories, respectively, affected).”
The following section reviews interventions that have been investigated for their potential to reduce PAHs in individuals with diabetes.

**Comprehensive disease management programs**

Comprehensive disease management programs are “care-based programmes managed by multidisciplinary teams of physicians (primary care and specialist physicians in some cases), and nurses (including nurse practitioners)”.[27]

An Australian initiative, the Restoring Health Program, has shown promising results using a multifaceted approach to diabetes management, heart failure and COPD.[32] Established at St Vincent’s Hospital in Melbourne, the Restoring Health Program is a multi-disciplinary model of care that incorporates a number of key elements: hospital-based key contact liaisons, community-based outreach nursing and allied health staff, outpatient disease-specific rehabilitation programs, and a rapid access outpatient clinic for urgent medical assessment. Emergency department presentations, hospital admissions and length of stay decreased significantly between six months pre-recruitment and six months post-recruitment for all three disease groups.[32]

A number of studies were carried out in health maintenance organisations (HMOs).[24] One large US initiative, entitled Diabetes Netcare, was evaluated in a group of 7 000 individuals with diabetes.[24] This program was based on a landmark multicentre trial (the Diabetes Control and Complications Trial), which showed beneficial outcomes for the diabetes population. However, the earlier program was expensive and the study was criticised for the way in which the sample was selected. Therefore, Diabetes NetCare aimed to offer a more cost-effective option with a representative sample of diabetes patients.

Using a population-based approach, which distinguishes it from other diabetes management programs, Diabetes NetCare had unrestricted access to their diabetes patients, including all care they receive, and their clinical information.[24] This allowed the HMO to manage all aspects of medical care, working with patients and their GPs to encourage best practice care procedures, and self-management behaviour in their patients. Patients and GPs received training specific to their needs, according to available GP performance data and patient care information. Nursing case managers were responsible for coordinating health care needs and facilitating service integration at the patient level.

Hospital admissions for members with diabetes decreased by 18 per cent over the trial period, and bed days fell by 21 per cent.[24] This was associated with a significant increase in the processes of care, such as foot and eye examinations, cholesterol tests and HbA1c monitoring. Over the period of the study, this resulted in savings of USD$50 per patient per month; and when broken down by source, savings were attributed primarily to the decrease in hospitalisations. However, some costs increased, particularly in relation to prescriptions.

Another comprehensive US disease management program for adults with diabetes involved two-hourly group meetings with a range of allied health professionals (overseen by two diabetologists) for a period of six months.[25] Patients also received support and ongoing management and telephone

---

1 Programs delivered within HMOs have the benefit of contracting medical and allied health practitioners under performance management agreements, which is not possible in fee-for-service environments like Australia. They are able to offer more integrated services due to this direct contractual relationship with providers.[24] It is also worth noting that HMOs must consider short term financial returns due to member turnover and competitive pressures.[24] For this reason, efficiency is a key part of these program evaluations.

2 Cited in Rubin et al. (1998)[24]
reviews with a nurse at least twice a month. The program successfully reduced HbA1c levels, improved patients’ ability to manage their own illnesses and significantly reduced the rates of hospitalisations and emergency department use. The rates of hospitalisations were around 80 per cent higher in people who did not use the program, compared to those who did.

A number of other managed care programs have been developed with similar positive results. These include programs for young people and the general population. Lower rates of hospitalisations were also observed in Aboriginal Australians participating in a disease management program that included a visiting specialist service and upskilling of Aboriginal Health Workers.

In contrast, several high quality studies that examined diabetes management programs resulted in no reduction in hospitalisations. One example is a randomised controlled trial of 169 patients from a Kaiser Permanente HMO. Patients met with a nurse-care manager to establish goals; they attended group sessions once a week for four weeks; and received telephone calls to manage medications and self-care activities. Although there were significant improvements in medical outcomes for the patients compared to usual care group, there were no significant changes in emergency room visits, or days of hospitalisation between the two groups. Importantly, the improvements occurred without increasing physician visits.

**Telehealth or ehealth programs**

Telehealth or ehealth programs are “applications or interventions that included use of telephones, modems, or other modes of distance communication as a primary means of health care provision”.

Although a number of research projects examined the impacts of different forms of telehealth interventions, most of them did not use PAHs as an outcome measure.

One study that did assess PAHs focused on diabetes management in the US Department of Veterans affairs using a telephone-based, nurse-coordinated service. Each day over a period of 24 months, patients completed a scripted survey regarding diabetes control and general health status. Nurse care coordinators monitored responses daily and made clinical judgements about whether patients should phone or make an appointment with their physician. The program was successful, with the treatment group exhibiting a statistically significant reduction in the likelihood of hospitalisations, both diabetes and non-diabetes related. It also resulted in fewer primary care clinic visits initiated by the care coordinator.

**Specialist clinics**

In some situations, it can be difficult to meet the needs of patients with diabetes in brief problem-focused office visits. Specialised diabetes clinics can potentially achieve better outcomes than usual generalist care as they can target the needs of diabetic patients. A number of high quality randomised controlled trials have been conducted to evaluate the use of specialist clinics for avoiding hospitalisations, with varying results.

Edward Wagner (who famously developed the Chronic Care Model) and his colleagues conducted a high quality trial for adults with diabetes. Practices were recruited to deliver half-day chronic care clinics for groups every 3–6 months. Each clinic consisted of an individual assessment, primary care physician, nurse, and pharmacist, as well as group education support. Intervention patients had slightly more primary care visits, but significantly fewer speciality and emergency room visits. At 24-month follow-up, specialist visits decreased significantly and hospital admissions decreased for both the intervention and control group, but this was not statistically significant.
Specialist outpatient clinics were more successful in reducing hospitalisations for diabetes. In the UK, Mahto and colleagues\textsuperscript{30} reconfigured a specialist inpatient diabetes clinic for use as an outpatient setting. This was an interesting intervention as it dealt with cases of varying complexity, promoted integration between the primary and acute care setting, and patients were triaged to see a diabetes nurse, GP, or specialist depending on their case. This approach reduced the number of inpatients by around 35 per cent, which included both diabetes and general admissions.

Whilst not strictly primary care, a similar study,\textsuperscript{131} which investigated the effect of a specialist diabetes team visiting hospitalised patients, may be applied in a primary health care environment. The team, consisting of an endocrinologist, diabetes nurse, social worker and dietitian, visited the patient daily. Compared to those who received no treatment, significantly fewer diabetes patients in the intervention group were readmitted for treatment; and importantly the length of hospital stay was reduced in those who were admitted. The high level of patient contact may be a key factor in the success of these studies.

Despite these reported successes, evidence (including a systematic review) suggests that while specialist clinics conducted by specialist diabetic nurses or physicians decreased the rates of hospital admissions in the short term, this was not maintained in the long term.\textsuperscript{132,133}

One example of a specialist clinic for complex diabetes care in Australia is the Inala Primary Care beacon practice in Queensland. Using the Primary Care Amplification Model\textsuperscript{k} of practice, Inala has significantly improved access to primary health care and patient outcomes, particularly for Indigenous patients with diabetes complications.\textsuperscript{134} However, it is unknown whether this model of practice has reduced the rate of PAHs for diabetes complications in this population.

**System level approaches**

Few projects that focused on systems level approaches measured hospitalisations as an outcome. Systems level interventions include “all interventions that were targeted at the level of health care delivery systems”.\textsuperscript{21}

A large survey of general practices in the UK\textsuperscript{135} found that patients attending practices with more facilities and more organised care had fewer hospital admissions. The kinds of facilities they measured were extensive, and ranged from technical skills, infrastructure, specialist GP skills, and the presence of allied health professionals relevant to diabetes management, such as dieticians and podiatrist. While the difference in hospitalisations between practices with and without facilities was statistically significant, the practical significance of this difference is minimal.

**Summary of interventions for diabetes**

In essence, high quality care for diabetes is based on proper prevention, coordination of care among a multidisciplinary team of health care professionals, enhanced patient-provider relationships, and patient self-management skills.

Given the small number of studies, it is difficult to make definitive statements about the effectiveness of diabetes interventions for reducing hospitalisations. Despite this, a number of trends have appeared in the research reviewed for this report. These are shown in Table 9.

\textsuperscript{k}PCAM is an extended general practice model that unites local general practices around a ‘beacon’ practice, and integrates with services, such as nursing, allied health, and specialist, according to local needs.\textsuperscript{134}
### Table 9: Summary of approaches to avoiding hospitalisations

<table>
<thead>
<tr>
<th>Approach</th>
<th>Key points</th>
</tr>
</thead>
</table>
| Disease management | • Individually tailored programs (for both the patient and practitioner) are successful  
                        • Multidisciplinary approaches are successful, and potentially less costly  
                        • There may a dose-response effect in terms of patient contact time, and the success of an initiative  
                        • A long-term perspective may be necessary for the success of diabetes interventions  
                        • Self-management per se is not sufficient to produce changes in hospitalisation. |
| Telehealth       | • There is some evidence of success with veterans, though more research is required to substantiate the findings  
                        • There is some reduction in hospitalisations for diabetes as well as comorbidities. |
| System level     | • More facilities and focus on diabetes in practices results in less hospitalisations, though this evidence is weak.  
                        • Specialist diabetes clinics appear to have success. These seem to be successful with both endocrinologists and GPs, though the latter is more cost effective. |

There are a few important factors that may help explain why some studies did not find significant reductions in avoidable hospitalisations. Firstly, interventions may only have small gains for some populations, particularly in elderly populations with multiple chronic diseases. This improvement may compound over time, as many of these interventions only looked at improvements over the short term.

Secondly, studies may vary in their definition of an avoidable hospitalisation, and also in the sample used (eg. age, comorbidities). This makes comparisons difficult. Specific interventions mentioned in this report were more helpful for some groups compared to others. For example, telemedicine was more useful for older people, but not for young people; and some interventions were not effective for some disadvantaged groups.\(^{11,130}\) Overall, education and self-management programs alone were not effective.

### PAHs for Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is a progressive and disabling disease, where destruction of lung tissue and narrowing of air passages leads to shortness of breath and reduced capacity for activity and exercise.\(^{136}\) The most important risk factor for COPD is cigarette smoking.\(^{136,137,138}\) Other risk factors include certain genetic characteristics and occupational exposure to dust and fumes; indoor and outdoor air pollution; and passive smoking may also play a role.\(^{136,137,138}\) COPD mortality decreased between 1997 and 2007 by 65 per cent. This may reflect reduced tobacco consumption followed by change in deaths due to COPD approximately 15 to 20 years later.\(^{136}\)

Females recorded a higher prevalence of 31 per 1 000 compared to males (27 per 1 000).\(^{136}\) There is increasing prevalence in older age-groups, with those aged 50-54 recording a prevalence of 32 per 1 000 individuals, while individuals aged 75 to 79 recorded a prevalence of 78 per 1 000.\(^{136}\) The disease is more prevalent among Indigenous Australians, with hospitalisation rates for Indigenous Australians nearly five times higher than non-Indigenous Australians.\(^{18}\)
COPD is the second leading cause of PAHs in Australia. In 2006-07, there were 52,560 hospitalisations where COPD was the primary diagnosis, which accounted for 0.7 per cent of total separations in that year. Higher hospitalisation rates occur among males, those living in rural and remote areas, Indigenous Australians, people from an English-speaking background and those living in lower socioeconomic status areas.

**Comprehensive disease management programs/coordinated care**

As part of the Department of Human Services Hospital Admissions Risk Program (HARP), a group of acute and community based health care providers located in the western suburbs of Melbourne formed a consortia to reduce the demand on hospital emergency services and improve health outcomes. Patients recruited to the project were assessed by “care facilitators”, who identified unmet health needs and provided information, advice and education for the patient concerning their condition and self-management. COPD participants in HARP significantly reduced their emergency presentations, admissions and hospital inpatient bed days by 10, 25 and 18 per cent, respectively. These patients also reported a significant reduction in symptoms. This program emphasises the importance of integrated care that is patient-focused, promotes greater self-management through education and delivers a continuum of care through the acute and community health sectors.

A number of other studies that investigated comprehensive disease management interventions found no effect. However, these studies either had a low frequency of patient contact, only taught self-management skills, which other studies have shown to be ineffective when used alone, or they sampled from a population who were potentially at high risk of hospitalisation.

A review of published evidence regarding the cost-effectiveness of multi-component COPD programs showed that programs that used three (decision support, self-management and delivery system design) or all four components of the Chronic Care Model (see Figure 4) showed statistically significant lower rates of hospitalisation.

![The Chronic Care Model](image)

**Figure 4**  The Chronic Care Model

---

1 The HARP program is discussed earlier in *Large-scale health interventions to reduce PAHs* and described in Table 7.
The success of multifaceted approaches has been validated by other studies. However, this review notes that there is a lack of economic evaluations, and some of these interventions are very costly.

The Restoring Health Program, which is described in detail in the section above on Comprehensive disease management programs for diabetes, has also shown positive results for those with COPD.

Further supporting the contention that singular approaches to disease management are not effective is a systematic review that was carried out to assess the effectiveness of self-management programs on COPD. Self-management education had no effect on hospital admissions, emergency room visits, days lost from work, and lung function. Similarly, an evidence based patient education tool found no effect on any measures, including hospitalisation.

Specialist clinics - Rehabilitation and physiotherapy
Two studies were identified that used outpatient rehabilitation and physiotherapy clinics. A simple pulmonary rehabilitation program based in the outpatient physiotherapy department at a district general hospital (Fairfield Hospital, Sydney) employed a physiotherapist under the supervision of a medical practitioner. This program lead to improved exercise endurance, improved quality of life ratings, and lower rates of hospitalisation and length of hospitalisations among participants. This occurred despite the fact that there were no improvements in lung function. Similar pulmonary rehabilitation programs have been shown to be effective. Although substantial evidence supports respiratory rehabilitation as part of COPD management, most studies did not assess the effect of rehabilitation on rates of PAHs.

In the UK, a community based COPD management program, which was led by a respiratory physiotherapist to improve home management of COPD, showed no reduction in length of stay, admission frequency or adjusted total hospitalisation days with COPD. However, patients with more severe COPD benefitted with a significant reduction in both length of stay and total hospitalisation days.

Summary of interventions for COPD
Overall, while the evidence was sparse, the most effective interventions to reduce COPD-related PAHs were HARP, the Restoring Health Program, and programs that implemented at least three of the four components of the Chronic Care Model. Specialist clinics for rehabilitation and/or physiotherapy for patients with COPD also reported some reductions in PAHs, though the evidence was not strong. Common features of successful approaches included a multidisciplinary care team, coordinated and integrated care, good continuity of care, a patient-centred focus and patient self-management.

Hospitalisations for dental conditions
Public health care programs have the potential to markedly reduce the incidence and prevalence of acute dental conditions, as these conditions are largely preventable and, when they occur, may be treated in the primary care setting. However, of all acute conditions, dental conditions make the largest contribution to hospitalisation; and they are the fourth leading cause of PAH (7.9%) after diabetes, COPD and angina. PAHs for dental conditions are particularly high in children under 15 years (24%); and in those aged 15-44 years (13%). The current high rate of hospitalisation for acute dental conditions suggests that patients are not receiving timely and effective diagnoses and interventions in the primary setting. Hence, it is likely that PAHs for acute dental conditions represents a lack of access to, or uptake of, primary dental health care. In addition, PAHs for dental
conditions in Bendigo in 2004-05 were associated with lack of fluoridation, low SES and rurality.\textsuperscript{148} After fluoridated water was provided, the rates of hospitalisation for dental conditions in young children decreased significantly (by 50%).\textsuperscript{149}

Dental health refers to the health status of the oral tissues and structures.\textsuperscript{150,151} Poor dental health generally manifests in dental decay, gum disease or tooth loss, but may also include oral cancer and trauma.\textsuperscript{152} These conditions may be caused or exacerbated by diet, poor oral hygiene, tobacco, alcohol, other medical conditions, medications and trauma.\textsuperscript{151}

Dental health is an integral aspect of general health, and may have significant ramifications for overall health status.\textsuperscript{17} Most oral diseases are not life-threatening; however, in 2006 a total of 613 patients died due to oral cancer, accounting for 0.5 per cent of all deaths during that period.\textsuperscript{17} Gum disease has been implicated recently in the development of various systemic diseases, including cardiovascular diseases, preterm delivery of low birth weight babies, diabetes, respiratory diseases and osteoporosis.\textsuperscript{153}

Additionally, poor dental health represents a significant financial burden on the Australian health system. Dental services were ranked eighth in the overall number of separations from public and private hospitals during 2007–08.\textsuperscript{154}

Dental diseases are largely preventable through population-level interventions, good oral hygiene and preventive dental care.\textsuperscript{152} Factors associated with disparities in access to dental health include geographical location, socioeconomic status, Indigeneity, disability and illness. People living outside of capital cities have less access to dental care and water fluoridation than those who live in capital cities.\textsuperscript{155} During 2004–06, tooth loss and poor oral health were more prevalent among people living outside of capital cities than in capital city residents.\textsuperscript{155} Aboriginal and Torres Strait Islander peoples are more likely than other Australians to have lost all their teeth, have gum disease, and receive less treatment. They are also less likely to have received preventive dental care and more likely to have untreated dental disease.\textsuperscript{156} Additionally, a recent report found that the likelihood of having private dental insurance was higher in people living in major cities (59%) than in those living in inner regional (47%) or outer regional areas (46%); and those with dental insurance visited a dentist more regularly and had better oral health than the uninsured.\textsuperscript{152}

People who utilise public dental care are likely to be socioeconomically disadvantaged, as they may be low income earners who are unable to afford private health insurance.\textsuperscript{154,157} A survey providing information on dental services received by 14 123 Australians showed that private patients received more preventive treatment than public patients, while public patients received more fillings, extractions and x-rays than private patients.\textsuperscript{158} The delivery of different service types for public and private dental patients may reflect public sector resource limitations, but may also suggest a greater reliance on emergency, rather than preventive, care.\textsuperscript{154} Adults with lower levels of household income and education may be more likely to suffer tooth loss and experience a greater social impact of dental conditions on their quality of life.\textsuperscript{158}

**System level approaches**
In April 2006, the National Health Service (NHS) in the United Kingdom amended the system of remuneration for NHS dentists.\textsuperscript{38} The traditional fee-per-item payment was changed to a banding system, whereby clinicians received payment of a single fee for the most expensive treatment provided. One study reviewed hospital admission rates for serious facial infections during the three years before and after the implementation of the new remuneration system.\textsuperscript{38} This study noted that
post-2006 access to primary dental care had been reduced, and that this led to an increase in patients presenting to hospital in a severe condition (see Table 10).

<table>
<thead>
<tr>

<td>21</td>
</tr>
</tbody>
</table>

In the three years following the remuneration system amendment, an additional 157 adults required admission and operation for spreading facial infections, which represented a 62 per cent increase. Additionally, there was a 66 per cent increase in the number of children presenting with facial spreading infections. Burnham and colleagues noted that facial infection should be considered a preventable disease in children, as good primary care should prevent the need for emergency admission to hospital.

**Summary of interventions for dental conditions**

No evidence was available to inform on the effectiveness of primary dental health care in reducing avoidable hospital admissions. However, one study clearly showed that reduced access to dental health led to an increased number of hospital admissions for preventable facial infections.

The Australian Government has introduced and maintained a number of programs and initiatives that aim to improve national dental health care. These are described briefly in Appendix D *Oral health initiatives*. However, as no effectiveness data are yet available, it is difficult to assess their impacts. Current national and international clinical practice guidelines prescribe broadly similar recommendations relating to primary dental health care, and these recommendations are generally well-supported by systematic review evidence. These can be found in Appendix E *Clinical practice guidelines for dental conditions*.

**Populations with high rates of PAHs**

Certain population groups consistently show elevated rates of PAHs. Characteristic of these groups is the fact that they tend to be overrepresented in the lower end of the socioeconomic spectrum. This section will focus on two key populations that show elevated rates of PAHs: People from low socioeconomic backgrounds and Indigenous Australians.

**People from low socioeconomic backgrounds**

There is consistent Australian and international evidence that shows individuals from low socioeconomic backgrounds have difficulties accessing primary health care, have poor health service utilisation and high rates of hospital admissions, particularly PAHs. Trends also indicate that overall health status, post-hospitalisation outcomes and life expectancy are worse among socio-economically disadvantaged individuals.

The terminology around this social determinant of health varies, with overlap between terms describing groups as ‘low income’, ‘low social class’, ‘low socio-economic status (SES)’, ‘impoverished’, or ‘disadvantaged’. These terms are defined by a range of criteria, including education, occupation, employment status, income or economic resources, population density and residential location, with measures often based on area-level or individual-level data.
postcodes, quintiles, gradients and/or national records (eg. the Australian Census). In an Australian review of PAHs, the Clinical Epidemiology and Health Service Evaluation Unit\textsuperscript{20} found that among the 23 studies analysed, most identified at least one of the socioeconomic factors as being linked to PAHs.

It must be noted that SES overlaps with a number of vulnerable population groups, with low SES commonly recorded among ethnic minority groups, rural and remote area residents, Indigenous Australians and adults over the age of 65.\textsuperscript{162} In addition to poor access, there are additional factors which may confound the relationship between SES and PAHs. These include not only high levels of a range of chronic diseases among disadvantaged populations but other correlates of health such as lifestyle and environmental factors. High rates of smoking and alcohol consumption, low levels of exercise and poor nutrition have all been linked with SES, along with adequacy of accommodation, air quality, education and socialisation, and psychological wellbeing in terms of depression, hostility and stress.\textsuperscript{55,63,162,164,165,166,167}

For the last 20 years, evidence has shown that rates of PAHs are consistently high among low SES groups. In the seminal US research by Billings and colleagues\textsuperscript{55}, findings indicated that residents of low income areas were four times more likely to have PAHs compared to areas with higher income. Though these authors recorded some influence of age with a peak in hospitalisations among the 25-44 year old cohort, results indicated that the nature of medical conditions, disease prevalence, substance abuse and physician practices had much less impact on PAHs than income.

These findings have been substantiated in Australia. In a rural Victorian sample, PAHs occurred at a rate 40 per cent greater in the lowest socioeconomic areas than in higher SES areas.\textsuperscript{8} In Australia more generally, residents in the most disadvantaged areas had 61 per cent more PAHs than individuals from the least disadvantaged areas.\textsuperscript{53,160}

**Initiatives to improve access to health care services**

There is a distinct lack of research examining interventions that assist individuals from low SES backgrounds. Instead, research that considers the role of SES is typically descriptive and examines its role in creating variations in rates.

The most commonly cited method of preventing PAHs among low SES groups centres on improving access to health care services. Billings et al.\textsuperscript{55} proposed that high hospitalisation rates among low SES groups may reflect a lack of timely and effective outpatient care and hence recommended that interventions should be directed at improving access to primary care. Given that people with a low SE background have particular difficulties with access, it can be reasonably assumed that interventions that promote access targeted at this group will reduce PAHs. Initiatives to improve access are described in Appendix F *Other approaches to reduce PAHs*. The following section describes a small number of intervention studies relevant to individuals with low SE backgrounds. While the research did not focus specifically on people from low SES as a target group, it was acknowledged as an important factor in reducing PAHs.

**System level approaches**

System level approaches can address different perspectives on PAHs. These may include policies to alleviate socioeconomic health inequalities such as implementing taxation to affect the distribution of wealth, income maintenance policies, and government investment in health care system infrastructure. Additional approaches relate to assessing the interaction between components of the health care system, and determining who is in greatest need of assistance in their associations with health services. Panattoni et al.\textsuperscript{168} investigated risk identification and the importance of ‘case finding’
to identify groups or individuals who are vulnerable and more likely to experience a PAH. The authors recommended the use of predictive risk models in Australia and New Zealand to predict health service usage and forecast disease occurrence. These models, which are used in the UK, could be applied in health care settings to identify those individuals who would benefit from preventive interventions.

**Multifactorial approaches**
A number of comprehensive management interventions have been trialled to improve patients’ health care and reduce the likelihood of hospitalisation. There are benefits to combining multiple approaches, as mentioned earlier with the *Chronic Care Model*. A literature review identified six priority areas for PAHs that cluster in three main types: person, program and place priority areas, which are shown below in Table 11.

**Table 11  Priority areas for interventions to reduce PAHs**

(Source: Muenchenberger & Kendall, 2010)

Muenchenberger and Kendall proposed that the best method for minimising PAHs was by promoting overall health. This would allow for a reduction in symptoms, better resources for self-management, access to health promotion tools and improved coordination of care. Comprehensive management involving multiples of the priorities listed above was advised as a more effective mechanism for preventing PAHs than single interventions.

The notion of combining methods has been embraced in programs offered both in Australia and internationally. One example is the *Restoring Health* chronic disease care model, which was...
implemented as part of the Victorian Government’s HARP initiative. The authors emphasised the importance of the psychosocial and cultural aspects of health among a group of individuals at high risk of potentially preventable chronic disease deterioration. The low-cost, multidisciplinary model incorporated hospital-based contacts, community-based outreach staff, disease-specific rehabilitation and a rapid access outpatient clinic. Implementation led to decreases in presentations to emergency departments, hospital admissions and reduced length of stay in hospital. Similar management care programs have been implemented with successes in other subsets of Australia’s Coordinated Care Trials, as well as in the USA. It is important to note that these initiatives did not specifically target individuals from low SE backgrounds, however they did sample from populations in which people with low SES were likely to be highly represented.

**Telehealth and Specialist Clinics**
There is little available evidence pertaining to the effectiveness of telehealth and specialist clinics for individuals with low SES. For telehealth, which is primarily used for improving access, reliance on phone and internet connections that are fundamental to this method is often problematic. Moreover, such technology is typically less accessible to low SES groups for cost and other reasons.

**Indigenous Australians**
The health status, incidence and severity of health conditions, and life expectancy of Indigenous Australians is significantly worse than the general Australian population. Socioeconomic disadvantage plays a major role and results in higher rates of risk behaviours, including misuse of tobacco, alcohol and other drugs, poor diet and low levels of exercise.

Compared to the general Australian population, previous research has shown that Indigenous Australians have higher rates of PAHs, which are associated with poor access to appropriate primary care. In the two-year period from July 2006 to June 2008, admission rates for PAHs were five times as high for Aboriginal and Torres Strait Islander peoples compared with other Australians. These data may reflect the problems faced by Indigenous Australians with regard to the location, affordability and cultural appropriateness of primary health care services. After adjusting for age differences between the two populations, Indigenous Australians accessed health care at similar rates to non-Indigenous Australians in 2009-10. Given that Aboriginal and Torres Strait Islander peoples have significantly poorer health, we should expect to see access to health services 2-3 times higher than for other Australians. On the contrary, age-adjusted data showed that Indigenous Australians received fewer Medicare services per 1 000 population overall for every type of service (except non-referred GP items and pathology).

It is important to note that the difference in rates of PAHs between Indigenous and non-Indigenous Australians has widened in recent years; and that the rates for chronic ambulatory care sensitive conditions, which account for 79 per cent of admissions have been increasing significantly. Adequate resources, community investment, appropriately trained staff and routine evaluation are required to address the disparity in rates of PAHs between Indigenous and non-Indigenous Australians.

Between July 2006 and Jun 2008, ambulatory care sensitive conditions accounted for 39 per cent of all hospital admissions (excluding those for dialysis) for Indigenous Australians. Differences in rates between Indigenous and other Australians are particularly striking for older age groups. For Indigenous Australians, vaccine-preventable conditions account for approximately 2 per cent of all hospital admissions.
PAHs; acute conditions for 23 per cent; and chronic conditions for 79 per cent of all PAHs\textsuperscript{172}. While the majority of PAHs (69%) for adults are related to diabetes complications\textsuperscript{172}, other significant conditions include COPD, convulsions/epilepsy and pyelonephritis. For children, the most common conditions related to PAHs are ear, nose and throat infections and dental conditions.\textsuperscript{173}

Compared with other Australians living in the same jurisdictions, PAHs for Aboriginal and Torres Strait Islander peoples were three times higher in New South Wales and Victoria; four times higher in Queensland, South Australia and Northern Territory; and 14 times higher in Western Australia.\textsuperscript{173} Between 2001-02 and 2007-08, data also showed a steady decline in PAHs for vaccine-preventable conditions (0.2% per annum); no significant change for acute conditions for Indigenous Australians; and a significant increase in PAHs for non-Indigenous Australians.

These trends highlight some of the barriers that Indigenous Australians face in accessing appropriate and effective primary health care.\textsuperscript{172}

**Initiatives to reduce PAHs**
Evidence has shown some benefits from a range of approaches. These include:

- comprehensive discharge planning involving all members of the multidisciplinary team and patient/family caregivers to develop a patient-centred plan\textsuperscript{44}
- adequate patient education and instruction, performing an accurate reconciliation of medications, establishing timely follow-up and developing an appropriately detailed discharge summary that is communicated to GPs and specialists in a timely fashion\textsuperscript{44}
- language and literacy-appropriate instructions and patient education materials to help in successful transition from hospital to home or community-based care. These documents must be brief and focused on critical information for the patient\textsuperscript{44}
- “Homelands” programs targeting central Australian Indigenous population. This group was already at an advantage, due to their more active lifestyle, with less reliance on a western diet. The focus of the program was on early detection, utilisation of available resources (dietary information, etc.) and implementation of ongoing planning involving patients and families to ensure quality care and minimisation of complications.\textsuperscript{45}

In many Indigenous communities, close relationships between health and education personnel permits the regular checking of children in schools for infectious conditions, hearing and respiratory problems, which results in early detection and minimises damage from chronic infections.\textsuperscript{45}

**Other approaches**
Screening for Indigenous patients at high risk of PAHs may help healthcare providers and organisations target resources for these patients and enable better planning for programs and interventions.\textsuperscript{44} These high-risk groups include: individuals using high-risk medications (antibiotics, anticoagulants; antipsychotics, etc.); those taking five or more medications; specific clinical conditions (advanced COPD, diabetes, heart failure, stroke and depression); prior hospitalisation typically including unplanned hospitalisations within the last 6 to 12 months; low literacy and poverty; reduced social network indicators; and poor access to health services.\textsuperscript{44}

There is a need for strengthening services that intervene earlier in the disease process, particularly are the primary care level; and address barriers that Indigenous Australians face in accessing these services.\textsuperscript{172} There is also a need for locally delivered health care that brings together primary health care, antenatal services, birthing support, and follow-up contact to families and communities, thus

\textsuperscript{172} The sum of these components is greater than 100 per cent as hospitalisations may be defined by multiple categories.
bridging the gap between mainstream services and local community groups.\textsuperscript{45} While the Inala practice has made significant progress in bridging this gap\textsuperscript{175}, the effect on PAHs is unknown.

To implement programs and interventions, it is necessary to ensure adequately resourced community health service infrastructure capable of supporting health care services.\textsuperscript{16} Aspects of primary care that are optimally positioned to sustainably reduce PAHs depend on the causal mechanisms underlying care-seeking behaviour and clinical decision-making in particular contexts.\textsuperscript{172}

**Unsuccessful approaches**

Several interventions and approaches that have failed to reduce PAHs include:

- Premature discharge or discharge to an environment that is not capable of meeting the patient’s bio-psycho-social needs – this is likely to result in rehospitalisation.\textsuperscript{44}
- Programs that are not culturally appropriate and contribute to miscommunication between Indigenous patients and their health care providers, which result in lack of patient control over language, timing and circumstances of interaction; differing modes of discourse; dominance of biomedical knowledge; cultural and linguistic distance and a lack of resources (such as trained interpreters).\textsuperscript{44}

**Avoidable readmissions**

Van Walraven et al.\textsuperscript{46} emphasised that readmissions to hospital are common, costly and often avoidable. Moreover, high rates of readmission are often related to the provision of suboptimal inpatient care and may be viewed as an indicator of quality of hospital care or a missed opportunity to coordinate care more effectively.\textsuperscript{176,177,178,179} To a lesser extent, other causes of readmission, such as the deterioration of intractable, chronic conditions, or the development of a new condition,\textsuperscript{180,181,182} may also be potentially avoidable where an inpatient’s worsening condition has not been recognised, discharge was ordered prematurely, or patients received inadequate post-treatment information.\textsuperscript{183}

The costs of hospital readmissions are substantial, with evidence from the US indicating that 18 per cent of Medicare patients are readmitted within 30 days of discharge from hospital, at a cost of $US15 billion.\textsuperscript{184} As the number of days post-discharge increases, the proportion of potentially avoidable readmissions increases (up to 14% at the 30-day period).\textsuperscript{184} Reducing hospital readmissions is a key objective of the US Affordable Care Act, which was enacted in March 2010; and the Medicare Payment Advisory Commission (MedPAC) recommended to Congress that hospitals with an “excess readmissions rate ratio”\textsuperscript{185} receive lower per case reimbursements.

*Hospitals must work much more closely with their physicians, interdisciplinary health teams, discharge and care managers, pharmacists, home health aides, and patients and their families to ensure optimal guided-care transitions to better coordinated care outside of the hospital to prevent readmissions and to improve outcomes (p9S).*\textsuperscript{185}

Research suggests that the risk for avoidable readmissions is greater for some populations, particularly those from low socioeconomic backgrounds.\textsuperscript{159} In addition, patients who recovered slowly after surgery, who suffered from multiple chronic comorbidities, or who were hospitalised within six months preceding a nonsurgical index hospitalisation, were more likely to be

\textsuperscript{0} Excess readmissions rate ratio is a ratio of observed to expected number of readmissions, based on a standardisation of risks and incidence rates for each risk.\textsuperscript{179}
Potentially avoidable hospitalisations in Australia: Causes for hospitalisations and primary health care interventions

readmitted. This study found that frequently readmitted patients were more likely to be older; have an urgent triage classification (categories 1 and 2); present with an unplanned return visit within 28 days of a previous visit; and have a diagnosis of mental illness, COPD, dyspnoea or chronic heart failure.

The role of primary health care and avoidable readmissions

A key question is whether effective management of discharge to primary health care has an impact on reducing avoidable readmissions. Research in this area is complicated by problems of definition and measurement. The rates of avoidable readmission are difficult to reliably assess due to the lack of a justified, specific time interval between a previous discharge and a readmission; and there is a lack of consensus on the methods used to judge the avoidability of a readmission.

There was little research about the extent to which primary health care interventions reduce avoidable readmissions; particularly readmissions related to conditions that fit the criteria for PAHs (see Table 3). However, some research indicates that absence of follow-up with a primary health care provider is associated with high rates of readmission. Analysis of Medicare claims data in the US showed that almost 20 per cent of Medicare beneficiaries were readmitted to hospital within 30 days of discharge; and more than half of these had not seen their doctor in the 30 days since discharge. While Jencks et al. estimated approximately 10 per cent of readmissions were planned (eg. cancer treatment), they suggest that ‘unplanned’ readmissions could be reduced with better discharge procedures and reliable follow-up care. This was supported in a recent US study, which reported a lower risk of readmission within 30 days among heart failure patients that received early outpatient follow-up after discharge and better coordination of care with their primary care provider. Paradoxically, one intervention designed to improve veterans’ access to primary care after hospital discharge resulted in increased readmissions, but greater satisfaction with care.

Initiatives to reduce avoidable hospital readmissions

The US MedPAC report suggests that primary health care practitioners and post-acute care providers play a critical role in reducing readmissions; and efforts to reduce avoidable readmissions should target discharge planning and post-discharge follow-up. They suggested that appropriate transition processes, including good communication, coordination, information exchange and engagement with patients’ primary care providers, are essential to reducing avoidable readmissions.

One way to reduce readmission is to identify those most at risk. The PARR algorithm, which was developed in the UK was applied to hospital admission data for all English patients admitted over a four-year period who had one of the identified reference conditions. The algorithm found that the key factors predicting subsequent readmission included age, gender, ethnicity, number of previous admissions, and the clinical condition. A similar validated tool, the LACE Index, was developed by Canadian researchers to quantify risk of unplanned readmissions within 30 days of hospital discharge.

Several programs aiming to reduce 30-day readmission rates have been developed; and three of these are listed in Table 12. One program that used an algorithm similar to the UK PARR algorithm

---

Due to incomplete data, this study could not determine what proportion of unplanned readmissions was avoidable.

PARR = Patients At Risk of Readmission.

LACE Index measures the following variables: Length of stay, Acuity of the admission, Comorbidity of the patient, and Emergency department use.
is the Reengineered Hospital Discharge (RED) program, which was based in an urban hospital that delivered assistance to a low income, ethnically diverse population. RED included a discharge planning intervention to avoid similar readmissions from occurring. The intervention included employing a specially trained nurse as a discharge advocate who assisted the patient with education both during their stay and around discharge, and organised services and follow-up appointments. In a similar program, which included patient education, self-management plan, discharge plan, and follow-up monitoring and support, an asthma nurse specialist intervention significantly reduced avoidable hospital readmissions for high health care users in the US. Compared to the usual care group, patients receiving the multi-faceted nurse-led intervention had 54 per cent fewer hospital readmissions for asthma.

Similarly, the BOOST and STAAR programs (see Table 12 for details) focus on the discharge process and follow-up post-discharge. While no rigorous evaluation of the BOOST program has been undertaken, evidence from case studies has shown improvements in reducing readmissions, length of hospital stay and mortality. Overall, these strategies show promising results in reducing hospital readmission and utilisation.

</thead>
</table>
| **Reengineered Hospital Discharge Program (RED)**<sup>47,48</sup> | The RED program comprises 11 elements:  
1. Patient education  
2. Schedule follow-up appointments  
3. Discussion about tests  
4. Organise post-discharge services  
5. Confirm medication plan  
6. Reconcile discharge plan with national guidelines and critical pathways  
7. Review appropriate steps regarding potential problems  
8. Ensure timely transmission of discharge summary to patient’s caregivers  
9. Assess patient’s understanding  
10. Provide written discharge plan for patient  
11. Post-discharge telephone reinforcement. |
| **Better Outcomes for Older Adults Through Safe Transitions (BOOST)**<sup>48</sup> | BOOST intervention includes:  
1. Communication with patient’s provider before discharge  
2. Re-designed discharge process, with patient PASS<sup>5</sup> form, assessment tools, checklists, tailored patient-friendly information and reminders  
3. TeachBack technique to ensure patients are aware of steps in the recovery process and what to watch out for; understand medication instructions and other information  
4. Follow-up phone call within 72 hours of discharge  
5. Follow-up appointment with provider. |
| **STate Action on Avoidable Rehospitalizations (STAAR)**<sup>47</sup> | STAAR program includes:  
1. Multi-state learning community to improve transitions of care  
2. Targeted technical assistance to address systemic barriers to reducing avoidable readmissions (uniform measurement strategy, policy and payment frameworks, financial analysis, community and cross-boundary coordination of care)  
3. Enhanced assessment of post-discharge needs  
4. Enhanced teaching and learning  
5. Enhanced communication at discharge  
6. Timely post-acute follow-up. |

<sup>5</sup> Patient PASS (Preparation to Address Situations (after discharge) Successfully) is a transition record provided to patients at discharge ([http://www.cha.com/pdfs/Quality/passhospital.pdf](http://www.cha.com/pdfs/Quality/passhospital.pdf)).
Conclusions

PAHs in Australia

Targeting a reduction in PAHs represents a number of possibilities for the Australian health care system. If primary health care interventions to prevent avoidable hospitalisations are successful, reducing PAHs may lead to: improved health system efficiency; improved cost-effectiveness; reduced pressure on hospitals; and most importantly, better care with less disruption to the lives of consumers.

Currently, PAHs comprise 8.6 per cent of all hospital admissions in Australia. The highest rate of all PAHs is for diabetes-related complications (24%). Other conditions that are highly represented in the list of PAHs are COPD, dehydration and gastroenteritis, and dental conditions. Chronic disease and acute conditions are almost equally represented, with fewer vaccine-preventable conditions. In Australia, almost all State and national policies have focused on tackling chronic conditions, with few focusing specifically on acute or vaccine-preventable conditions.

Using PAHs as an indicator of the effectiveness of primary health care

While it is true that PAHs are related to access to primary health care services, many other factors that are less mutable to intervention may also contribute to a hospitalisation. Beyond access, the strongest influences on rates of hospitalisations are:

- socioeconomic status
- age
- ethnicity
- health status
- comorbidity
- continuity of care
- rurality
- mental health problems

Due to the propensity for these factors to influence the rates of PAH, an extensive US review suggested that the rates of PAHs should be adjusted for demographic factors. The same review also suggested that PAHs should be interpreted as a collective set, rather than being broken down into disease-specific groups.

Despite caution against interpreting PAHs as a set, research suggests that disease-specific interventions may be more successful than more generalist interventions. Unfortunately, most of the research on PAHs is descriptive with little intervention research; and mostly focused on diabetes. The diversity in methodologies, populations, and disease focus means it is difficult to draw generalisations from the research. There are a number of large-scale programs or initiatives that have been developed and implemented in Australia with focus on PAHs. However, few of these have been evaluated, and of those that have been evaluated, changes in PAHs were not included as an outcome measure.

Future directions for interventions in Australia

Some promising large-scale programs were identified in Australia. These were the Hospital Admission Risk Program (HARP), Chronic Disease Management in Victoria, the NSW Community Acute/Post-
Acute Service, and the Victorian Early Intervention in Chronic Disease in Community Health Program. These programs have a number of characteristics in common:

- a focus on early intervention for those who are at risk
- care coordination
- a focus on equity and access
- multidisciplinary care
- developing systems that focus on disease management in the medium to long term.

These interventions also focused chronic disease, rather than acute or vaccine-preventable conditions.

A number of studies reviewed show that while the clinical indicators of disease may improve, PAHs for that disease may not necessarily decrease. Conversely, a program may not improve clinical indicators, but it does reduce PAHs. This suggests that there are other aspects of primary care disease management that reduce PAHs, such as assisting individuals to manage their symptoms better or providing advice about when hospital visits are appropriate.

Similarly, the most successful disease-specific interventions focused on care coordination and comprehensive disease management. A number of themes were identified from successful comprehensive disease management programs:

1. Individually tailored approach. Mostly this is for the patients, though also for the practitioners in terms of professional development to deliver high quality care.
2. Nurse coordinator. Many cost-effective programs had nurses coordinating the ongoing management of the patient and their health care services.
3. Multidisciplinary workforce. Many programs included input from podiatrists and patient educators.
4. Long-term programs. Many of these programs extended for longer than six months. This is not typical of other intervention studies.
5. Reduced hospitalisations, though increased primary health care services. Increased GP presentations and pharmaceuticals.
6. Nurses in key role. Many of these programs also used nurses, rather than GPs or specialists. This may point to more contact time between the patient and the nurse, or skill development in a particular area of illness leading to improved patient outcomes.
7. Diabetes. Some success was seen with specialist diabetes outpatient clinics.
8. COPD. Hospitalisations were significantly reduced with the use of physiotherapy and rehabilitation clinics.

With dental conditions, and people from low SE backgrounds, hospitalisations were due largely to difficulty in accessing care. Given the relationship between access and avoidable hospitalisations, it is possible that any program that improves access will result in reduced hospitalisations. One review identified six factors, including improved socioeconomic opportunity as a factor in reducing PAHs. Other factors include:

- symptom management
- creating supportive environments
- self-management support
- service delivery and coordination
- local liveability.

Muenchberger and Kendall also identified factors very similar to those proposed in Wagners’ Chronic Care Model. Importantly, research on the Chronic Model suggests that no single factor alone is
likely to be effective and reduce PAHs, rather, at least three or four factors should be part of effective interventions.

Regarding readmissions, limited research suggests that readmissions may contribute substantially to the rates of PAHs. However, it is difficult to estimate given the lack of clear definition of what constitutes a readmission. Nonetheless, a number of studies have identified reliable algorithms to identify those most at risk of readmission. These patients have successfully avoided readmission through redesigning of the discharge planning processes, including linking people more effectively to the primary health care environment.

Finally, it is important that while hospital visits decrease, the burden on primary health care often increases. Given that primary health care is a more cost-effective alternative, it follows that primary health care practitioners need support and resources to develop the capacity to deliver these extra services.

Appendices

Appendix A  Expanded methods

Definition

A range of definitions have been used for PAHs depending on the context and country. The more common terms used are “ambulatory care sensitive conditions”, “potentially preventable hospitalisations” or “potentially avoidable hospitalisations”. Avoidable hospitalisations are distinct from preventable hospitalisations, the latter of which represents a broader range of conditions or illnesses that are preventable with population based health promotion efforts. Some research also includes adverse events that result from medical mismanagement rather than the condition itself though these are excluded in this report as they were rarely included in the research reviewed.

The approach used in Australia (including the Health Performance Framework and AIHW) is based on the “potentially avoidable hospitalisations” framework. While there may be some minor differences in definitions, most research uses the terms interchangeably. Therefore, for consistency throughout this report, we have used PAHs, which are defined as:

... conditions for which hospitalisation is considered potentially avoidable through preventive care and early disease management, usually delivered in a primary care setting, for example by a general medical practitioner, or at a community health centre.

This definition of PAHs was chosen as it adheres most closely to that used by the Australian Institute of Health and Welfare, on which the Australian Health Performance Framework is based. Many important agreements (including COAG) in Australia are based on this definition.

Procedure

This report followed a ‘rapid review’ format. Rapid reviews are a short review that focuses on research evidence, with a view to facilitating evidence-based policy development. Due to the short timeframe for this review (8 weeks), searches and critical appraisal of the literature were not systematic or comprehensive. Search terms included a combination of text words and MeSH terms for PubMed; however, in order to obtain the most relevant material quickly, the combination of terms varied across the grey literature, such as Google Scholar, and for different databases. Consequently, replication of this review is likely to result in a different literature base.

The issue under investigation centred on interventions to decrease the rates of PAHs. Specifically, this focused on

What does the local and International research literature tell us about hospital admissions that are potentially avoidable related to improved primary health care service delivery?

A number of parameters were placed on the content in order to enable a practical and comprehensive review:

- Interventions were investigated at multiple levels - eg. patient through to systems levels
- Evaluation of the clinical merit of interventions was beyond the scope of this review
- Emergency department presentations were excluded
- The search strategy for this review did not explicitly include avoidable hospital readmissions. However, a brief section on potentially avoidable readmissions is included as there was some overlap in the literature
Hospitalisation due to adverse events, including medication errors, was excluded.

The literature was limited by time periods, as much of the research on PAHs was conducted in the early 1990s and the authors of this report did not want to lose this information. Likewise, no limits were imposed on location or setting, though different environments such as research that took place in the US, or within Health Maintenance Organisations have been flagged as such.

Both grey and peer reviewed literature were included in this report.

Caveats and Limitations
There are a number of caveats and limitations that should be considered when reading this report. These include:

- **Non-systematic or exhaustive search**: Whilst significant effort was made to obtain all relevant literature on the topics addressed in this report, given the time limitations and the large scope of the topic, the approach was not systematic.

- **Predominantly Australian focus**: The research was drawn primarily from studies conducted within Australia. In some respects, this was a deliberate strategy, as the nature of the report necessitated the use of Australian statistics and approaches. However, International wisdom pertaining to initiatives and interventions may have been lost as restricted timeframes precluded conducting a comprehensive search for relevant International interventions.
Appendix B  Avoidable hospitalisations included in the Australian Health Performance Framework

Appendix D  Oral health initiatives

Several national primary dental health policies and initiatives are underway; however, these are at varying stages of completion and effectiveness outcomes are not yet available. Examples of these initiatives have been briefly detailed below.

**Closing the Gap**
Under the Northern Territory National Partnership Agreement, the Australian Government funds a range of specialist and allied health follow-up services, including oral assessment and dental treatment. The Closing the Gap initiative aims to assess all Indigenous children under 16 years of age who have been referred for dental follow-up. At December 2009, 1 594 of the 3 223 children referred for dental follow-up had been assessed at least once.

**Medicare Allied Health and Dental Care Initiative**
This initiative commenced in July 2004. It allows people with chronic conditions and complex care needs, who are being managed by a general practitioner under a Chronic Disease Management plan, to access Medicare rebates for allied health services including dental specialists.

**Medicare Teen Dental Plan**
This initiative commenced in July 2008 and improves the affordability of maintaining good teenage dental health in eligible families. The service provides a preventative oral examination which may include x-rays, scale and clean, fluoride treatment, provision of oral hygiene instructions and/or dietary advice, or fissure sealing.

**Chronic Disease Dental Scheme**
This scheme allows eligible patients to access a range of Medicare dental items, via referral from a general practitioner. To be eligible, patients must have a chronic medical condition and complex care needs and their oral health must impact on, or be likely to impact on, their general health.

**Better Oral Health in Residential Care training**
This training program commenced in December 2009 and aims to provide carers with an increased awareness and understanding of oral hygiene issues.

**Healthy Start for School Initiative**
This initiative, which commenced in July 2011, relates to parents who receive an income support payment during the year their child turns four, and who are receiving Family Tax Benefit Part A. The four-year-old child receives a mandated health evaluation (including an oral health assessment) to ensure that they are healthy, fit and ready for school.

**Healthy Mouths, Healthy Lives – Australia’s National Oral Health Plan 2004-2013**
This plan aims to improve health and wellbeing across the Australian population by improving oral health status and reducing the burden of oral disease. The plan aims to address a number of action areas: across the Australian population; children and adolescents; older people; low income and social disadvantage; people with special needs; Aboriginal and Torres Strait Islander peoples; and the

---

1. Replaced the Enhanced Primary Care plan in 2007.
dental and oral health workforce. The plan details a number of short-, medium- and long-term strategies for improving oral health across each of these action areas.

**Denticare Australia**

A 2009 report by the Australian Government National Health and Hospitals Reform Committee recommends the national provision of a universal scheme for access to basic dental services.\(^{199}\) Under this scheme (‘Denticare Australia’), all Australians could elect to have basic dental services (prevention, restoration, and the provision of dentures) paid for by Denticare via either private health insurance or public dental services. This report also recommends that graduating dentists and oral health professionals undertake internships, to receive broader clinical experience and training.

</tr>
<tr>
<td></td>
<td>• Members of the dental team should support and promote breastfeeding according to current recommendations. 200,201</td>
<td>Harris and colleagues 202 found that one-to-one dietary interventions in the dental setting may change patient behaviour, although the evidence was greater for interventions aiming to change fruit, vegetable and alcohol consumption than for those aiming to change dietary sugar consumption.</td>
</tr>
<tr>
<td></td>
<td>• Infants should not be put to bed with a feeding bottle (Armstrong et al 2008); drinks containing free sugars, including natural fruit juices, should never be put in a feeding bottle. 200</td>
<td>Lingstrom and colleagues 203 found that the evidence for the use of sorbitol or xylitol in chewing gum, or for the use of invert sugar, is inconclusive. They found that adding calcium phosphate or dicalcium phosphate dihydrate to chewing gums had no caries-preventive effect.</td>
</tr>
<tr>
<td></td>
<td>• Cheese is a good high energy food for toddlers as it is non-cariogenic and may be actively protective against caries. 7,200</td>
<td></td>
</tr>
<tr>
<td></td>
<td>• Free sugars intake should not exceed 10% of the total dietary energy intake (including alcohol) nor 11% of the total food energy (excluding alcohol). 201 Foods, beverages and confectionery containing free sugars should be minimised and, if possible, restricted to meal times. 200,201</td>
<td></td>
</tr>
<tr>
<td></td>
<td>• Confectionery and beverages containing sugar substitutes are preferable to those containing sugars. 200 Health professionals should check if a medicine contains sucrose and offer sugar-free alternatives wherever possible 201</td>
<td></td>
</tr>
<tr>
<td></td>
<td>• The frequency of acidic drinks such as fruit juices, squashes and carbonated drinks (including diet and sports drinks) should be reduced. 201</td>
<td></td>
</tr>
<tr>
<td><strong>Fluoride</strong></td>
<td>• Children should have their teeth brushed with fluoride toothpaste. 200 Toothpaste containing fluoride concentrations of 1 000 ppm (parts per million) +/- 10% should be used by pre-school children. 200</td>
<td>Walsh and colleagues 206 found that the caries preventive effect of fluoride toothpaste increases significantly with higher fluoride concentrations. This was only significant for fluoride concentrations of 1 000 ppm and above.</td>
</tr>
</tbody>
</table>
Topical fluoride varnish should be applied to the dentition at least twice yearly for preschool children assessed as being at increased risk of dental caries. Adults should brush twice daily with fluoridated toothpaste. Adults should use fluoridated toothpaste with at least 1350 ppm fluoride. Dietary fluoride supplements are recommended for children at high risk of developing caries, and are not recommended for children who are at low risk of developing caries.

Marinho and colleagues found that fluoride mouthrinse, gels or varnishes used in combination with toothpaste, compared to toothpaste alone, had a significant effect on caries reduction ($p=0.01$). Additionally, the combined use of fluoride gel and mouthrinse in comparison to gel alone had a significant effect ($p=0.02$). However, another systematic review found that the use of fluoride toothpastes had a similar degree of effectiveness to mouthrinses or gels for the prevention of dental caries in children (Marinho et al 2004a).

Bonner and colleagues compared slow-release fluoride devices with an alternative fluoride treatment, placebo, or no intervention in children, and found that caries increment was significantly lower in the intervention group than in the placebo group.

McDonagh and colleagues found that fluoridation of drinking water led to reductions in the incidence of caries, although these reductions were smaller than previously reported. The prevalence of fluorosis was found to be highly associated with the concentration of fluoride in drinking water.

Yeung and colleagues compared fluoridated milk with non-fluoridated milk at three year follow-up, and found that fluoridated milk was beneficial to the permanent dentition of school children.

Marinho and colleagues found that the supervised regular use of fluoride mouthrinse at two main strengths and rinsing frequencies was associated with a clear reduction in caries increment in children ($p<0.0001$).

Tubert-Jeanin found that when compared with no fluoride supplement, the use of fluoride supplements may be associated with a reduction in caries increment in permanent teeth. The effect of fluoride supplements on deciduous teeth...
was unclear. When compared with the administration of topical fluorides, no differential effect was observed. Additionally, Ismail and Hassan\textsuperscript{213} found weak and inconsistent evidence that the use of fluoride supplements prevents dental caries in primary teeth, and some evidence that such supplements prevent caries in permanent teeth. They noted that mild-to-moderate dental fluorosis is a significant side effect of oral fluoride supplementation.

| Sealants          | Children and adolescents who are assessed as being at high caries risk should have resin-based fissure sealant applied and maintained in pits and fissures of permanent teeth. Adults who are assessed as being at high caries risk should have resin-based fissure sealant applied and maintained in pits and fissures of permanent teeth.\textsuperscript{214} Ahovuo-Saloranta and colleagues\textsuperscript{215} compared the effectiveness of sealants with no sealant, or sealants from different classes of materials, for preventing occlusal caries in children and adolescents. After 4.5 years the sealed permanent molar teeth of children aged 5–10 had over 50% reduction in decay compared with teeth without sealants. One included study with longer follow-up showed that after nine years only 27% of sealed tooth surfaces were decayed compared with 77% of tooth surfaces without sealant. Azarpazhooh and Main\textsuperscript{216} concurred that sealants should be placed on the primary molars of children who are susceptible to caries, and noted that they should be placed as part of an overall prevention strategy based on assessment of caries risk. Hiiri and colleagues\textsuperscript{217} found that pit and fissure sealants were significantly more effective than an application of fluoride varnish every six months in preventing occlusal decays of first molars at 23 months, at four years and nine years. |
**Toothbrushing**

- Children should have their teeth brushed at least twice a day, using no more than a smear or small pea-sized amount of toothpaste.\(^{200,204}\)
- Toothbrushing should commence as soon as the primary teeth erupt.\(^{200}\)
- Children’s teeth can be brushed with either manual or powered toothbrushes as an effective means of administering fluoride.\(^{200}\)
- Brush last thing at night and on one other occasion.\(^{204}\)
- Spit out after brushing and do not rinse.\(^{200,204}\)
- Clean interdentally using interdental brushes or floss.\(^{204}\)

Robinson and colleagues\(^{218}\) found that brushes with a rotation oscillation action removed plaque and reduced gingivitis more effectively than manual brushes in the short-term and reduced gingivitis scores in studies over three months. Deacon and colleagues\(^{219}\) found some evidence that rotation oscillation brushes are more effective at reducing plaque and gingivitis more than side-to-side brushes in the short term; however, this difference was small and its clinical importance was unclear. Sambunjak and colleagues\(^{220}\) found that flossing plus toothbrushing showed a statistically significant benefit compared to toothbrushing alone in reducing gingivitis at one, three and six months. They also found that flossing plus toothbrushing may be associated with a small reduction in plaque at one and three months.

**Dental recall checks; scaling and polishing**

- First examination at the eruption of the first tooth and no later than 12 months. Repeat every six months or as indicated by child’s risk status/susceptibility to disease.\(^{221}\)

Beirne and colleagues\(^{222}\) found that there was insufficient evidence on the potential benefits and harms of altering the recall interval between dental check-ups, or to support or refute the practice of encouraging patients to attend for dental check-ups at six-monthly intervals. The same study found that there is insufficient evidence on the beneficial and adverse effects of routine scaling and polishing for periodontal health, and on the effects of providing this intervention at different time intervals.\(^{222}\)
Appendix F  Other approaches to reduce PAHs

Initiatives to improve access, as a secondary means of avoiding hospitalisation

Despite Ho et al.\(^\text{164}\) suggesting that similar in-hospital mortality rates between the highest and lowest SES groups denoted equity of access in the Western Australian public health care system, the majority of evidence in the literature suggests that low SES is strongly related to difficulties accessing health care; one of the overarching perceptions is that “equal need [does] not equate to equal utilisation”\(^{41}\) p.74. This is associated with the inverse care law described earlier and the mismatch between availability of, and need for, health care. Ansari et al.\(^8\) proposed that “the removal of disparities in health care access between ... socioeconomic groups ... will have the potential to improve health outcomes in the population and reduce demand on hospital services” (p. 41). Access incorporates economic (eg. cost, transport, child care), structural (eg. informed about services, eligibility) and personal/cultural barriers (eg. health literacy, language, confidence)\(^{55,56,160,223}\) and each of these could be targeted when improving circumstances for low SES groups. Watson\(^223\) focused on methods of increasing uptake of services and retaining participants among families vulnerable due to abuse; and highlighted important components of access as the relationship between the service provider and the individual, communication style, practical support, ease of physical access to programs, continued contact/follow-up and approachability. In the US, Epstein\(^224\) actively tested the access hypothesis and found that the availability of free public ambulatory clinics in medically underserved areas was able to reduce preventable hospitalisations among low income groups.

However, there is evidence that interventions to improve access and efficacy of primary care among low SES individuals must be strategic. Chan et al.\(^150\) conducted an RCT assessing the value of a multidisciplinary team approach to primary care among women in low SES areas and found no significant differences between intervention participants and controls on any measure of mental health, general health or quality of life. Instead of the improvements in health they expected, these authors found that in some cases wellbeing declined as the patients’ attention was directed at the difficulties they faced in their lives and the length of the program did not allow for adequate processing of such emotions or the bolstering of support to tackle challenges. Nevertheless, Bindman et al.\(^3\) indicated that when addressing factors affecting health and preventable hospitalisation, improving access is more likely to be effective than changing individuals’ propensity to seek care or altering physicians’ behaviours. Perhaps there simply needs to be greater consultation on what low SES groups require. Additional factors affecting access relate to health insurance, concession cards, bulk-billing and subsidised medications\(^54\). Korda et al.\(^163\) found that in Australia concession cards were able to reduce socioeconomic inequality in general practice use among middle-aged women but had no effect on specialist care, while some of the inequality in allied health service use was attributed to private health insurance. Once again it follows that improving access to different health services will likely prevent PAHs.

Health Prevention

Despite some question as to the effectiveness of health promotion among disadvantaged groups\(^162\), one method for targeting PAHs among low SES groups has been to consider health prevention and reducing risk factors for PAH thereby indirectly addressing PAHs. As indicated by Cable\(^225\) “removing financial barriers is critical but may be insufficient for reducing preventable hospitalisations if other barriers are not also addressed” (p. 66). Evaluations of these strategies do not typically measure avoidable hospitalisation as outcomes and most do not specifically describe how they impacted upon low income groups, yet consistently these approaches mention that the program may be of benefit to low SES groups due to increased prevalence of health risk behaviours among this population.
There have been a number of interventions delivered to reduce rates of substance use, including smoking, alcohol consumption and both legal and illicit drugs\textsuperscript{166}. The programs have been of mixed quality and produced mixed results but unanimously emphasised the need to consider vulnerable populations who are prone to high rates of substance abuse. Interventions addressed all age groups and included family home visits, parent education, school-based education, peer interventions, sport and recreation programs, mentoring, mass media campaigns and law enforcement. The idea of many of these strategies is to reduce incidence of substance use and prevent further health risks.

Substance use has been associated with cardiovascular health, cancer and injury; hence it seems logical that there may be an association with these kinds of lifestyle factors and PAHs. Loxley et al.\textsuperscript{166} suggested that structural and legislative strategies are the most effective methods of addressing health inequalities. These authors also suggested targeting vulnerable and disadvantaged groups, offering support to families, encouraging healthy development and providing health education across a range of age groups.

In considering smoking specifically, acknowledging an association between SES and cardiovascular disease (CVD), Beauchamp et al.\textsuperscript{226} sought to investigate the efficacy of CVD interventions among disadvantaged groups both in Australia and internationally. Overall their review identified limited benefit of CVD interventions among low SES groups. The authors assessed smoking reduction strategies, absolute risk assessment, secondary prevention medications and rehabilitation, and heart failure self-management programs. There was some merit in the notion of increasing tobacco taxation as a method for reducing smoking prevalence but the availability of cheap tobacco from alternative sources (ie. black-market) proved a barrier to this strategy. Nicotine replacement therapy had short-term benefits but underlying addiction and continuing psychosocial influences prevented its long-term efficacy. Cardiac rehabilitation and heart failure self-management were also considered beneficial on the whole though access and health literacy were barriers requiring attention. In contrast, absolute risk assessment models were perceived as potentially underestimating the breadth of the problem. The authors recommended intervention across all stages of the CVD continuum with an emphasis on combining community or population-based interventions with high-risk group-directed strategies.
